ABSTRACT

While stereo music reproduction was a dramatic advance over mono, recently a transition to multi-channel audio has created a more involving experience for listeners. A new method to enhance the conversion from stereo to multi-channel sound reproduction is presented. A better sound distribution to the surround channels is achieved by using cross-correlation technique, and a stable center image is obtained using Principal Component Analysis.

INTRODUCTION

Since the presence of Digital Versatile Disk (DVD) and Super Audio CD (SACD), multi-channel audio has become popular in the sound systems for consumer use today. This paper presents a new method which converts two-channel stereo to multi-channel sound reproduction, using a three dimensional representation (henceforth referred to as space mapping).

Although many authors have introduced multi-channel sound systems with a large number of channels, we restrict ourselves to a home cinema setup which has been investigated to be sufficient with five channels. The desired setup is shown in Fig. 1, where L, C, R, S_l, S_r refer to left, right, center, left-surround, and right-surround channel, respectively. This setting is adopted from the ITU multi-channel configuration [1], with three loudspeakers placed in front of the listener, and the other two at the back.

By use of Principal Component Analysis (PCA) [2] we develop an algorithm that produces a vector which indicates the direction of both dominant signal (g) and remaining signal (q) as shown in Fig. 2. Note that these two directions are perpendicular to each other creating a new coordinate system. These two signals are then used as basis signals in the matrix encoding.

PROPOSED METHOD

The algorithm presented in this paper offers two improvements above existing multi-channel techniques. Firstly, a problem associated with channel cross-talk is reduced, and therefore sound localization is better achieved. The latter gives more space to the listener to enjoy the offered program.
Fig. 1: ITU reference configuration [1]. The reference listening position (sweet spot) is indicated by x. Left and right channels are placed at angles ±30° from C, and the two surround channels are placed at angles ±110° from C.

rather than restricting the listener in the sweet spot\(^1\).

Secondly, a better sound distribution to the surround channels is achieved by using a cross-correlation technique, while maintaining energy preservation. Energy preservation criterion is an important constraint that has been used to design multi-channel matrices [4]. One reason is it is a factor in backward and forward stereo compatibility. Furthermore, the preservation criterion ensures that all signals present in the two-channel transmitted signals are produced at a correct power level, so that the balance between the different signals sounds in the recording is not disturbed.

\(^1\)This algorithm has been a patent pending [3].

The center channel

We consider the three-channel approach first. It is known that the sound quality of stereo sound reproduction can be improved by adding an additional loudspeaker between each adjacent pair of loudspeakers. For example, an additional center loudspeaker \(C\) can be fed with the signal \(\frac{1}{2}(x_L + x_R)\), where \(x_L\) and \(x_R\) represent signals from left and right channel, respectively. A major drawback of this approach is that crosstalk with left and right channels is inevitable, and therefore narrowing the stereo image.

Fig. 2: A Lissajous plot of stereo signal forming. The dashed lines represent a new coordinate system based on both the dominant signal \(y\) and remaining signal \(q\).
In the following, we derive a center channel's gain using the
direction of a stereo image which is time varying. The dashed
direction corresponding to the dominant signal \( y \) shown in Fig.
2 represents the image direction for left and right channel in
stereo signals. It can be shown that this direction can be
detected by using a simple direction sensing algorithm. At each
iteration of the algorithm, the weights at time instant \( k \), i.e. \( w(k) = [w_l(k)\ w_r(k)]^T \), corresponding to the left and
right channel respectively, are computed using the following
equation:
\[
w(k) = w(k - 1) + \mu(k) \left[ x(k) - w(k)y(k) \right],
\]
where
\[
y(k) = w^T x(k), \]
\[
x(k) = [x_L(k) x_R(k)]^T,
\]
and the step size is signal dependent as
\[
\mu(k) = \frac{C}{y(k) + C},
\]
where \( C \) is a constant typically 0.001.
The direction of a stereo image in terms of angle in radians
can then be computed using,
\[
\alpha(k) = \arctan \left( \frac{w_R(k)}{w_L(k)} \right).
\]
Figure 3 shows the fluctuations of the angle \( \alpha \) computed from
a DVD movie fragment where abrupt changes from one channel
to the other are present. Note that the horizontal axis represents
the number of blocks \( B \) where each block contains 512 samples.

Now we can represent a pair of stereo signals using this vector.
This is a vector of unit length having the right channel gain in
the horizontal axis, and the left channel gain in the vertical axis,
as shown in Fig. 4a. To map this stereo vector onto a three-channel vector,
doubling the angle \( \alpha \) is performed. This transformation can be computed using simple sine and cosine rules:
\[
c_t = w_2^2 - w_1^2, \]
\[
c_c = 2w_1 w_r, \]
which is depicted in Fig. 4b. Note that this transformation
works only for nonnegative \( \alpha \). For negative \( \alpha \), a multiplication
by a factor two results the vector to be in a lower quadrant,
and therefore no gain can be derived for the center channel.
To overcome this problem, extra information should be used
which is described in the next section.

The surround channels

The surround channels are generally used for creating ambience
effects as by music. While for applications in the film industry the surround channels are used for sound effects. A
common technique for ambience reconstruction is the use of
delayed front channel information for the surround channels.
Dolby Pro Logic for instance, has delayed the surround sounds
so as to arrive at the listeners ears at least 10 ms later than the
front sounds [4].

Environmental and ambience effects can also be computed by
considering left and right channel variations \( x_L - x_R \) in the
encoded signals. This variation is usually referred to as the
\textit{anti-phase} components, the amount of which can be repre-
sented by the remaining signal \( q \) (Fig. 2). However, it can

be expected that when the amount of the dominant signal equals
to that of the anti-phase components, an ambiguity appears
since there is no way to determine the direction ve-
tor uniquely. This state can be visualized that the distribution
in Fig. 2 is no longer an ellipse but a circle \( y = q \), causing
\( \alpha \) to be arbitrary.

Obviously extra information is necessary when dealing with
this sort of ambiguity. In this paper we propose to use a
known technique to measure the amount of anti-phase com-
ponents by use of the correlation coefficient which can be com-
puted recursively by using only a few arithmetic operations
as [5],
\[
\hat{\rho}(k) = \hat{\rho}(k - 1) + \gamma [2x_L(k) x_R(k) - (x_L(k)^2 + x_R(k)^2) \hat{\rho}(k - 1)],
\]
where \( \gamma \) is the step size determining the time constant, and
the symbol ‘\( \hat{\cdot} \)’ is used to denote that it is an estimation of the
true \( \hat{\rho} \).

Since
\[
-1 \leq \hat{\rho} \leq 1,
\]
it is possible that the anti-phase components exceed the domi-
nant signal \( |y| < |q| \). In this case we treat the input signals
as uncorrelated, and it is therefore
\[
\rho_\theta = \begin{cases} \rho \quad & 0 \leq \rho \leq 1 \\ 0 & \text{otherwise} \end{cases}.
\]

Space mapping

To avoid this problem, extra information should be used
which is described in the next section.

The surround channels

The surround channels are generally used for creating ambience
effects as by music. While for applications in the film industry the surround channels are used for sound effects. A
common technique for ambience reconstruction is the use of
delayed front channel information for the surround channels.
Dolby Pro Logic for instance, has delayed the surround sounds
so as to arrive at the listeners ears at least 10 ms later than the
front sounds [4].

Environmental and ambience effects can also be computed by
considering left and right channel variations \( x_L - x_R \) in the
encoded signals. This variation is usually referred to as the
\textit{anti-phase} components, the amount of which can be repre-
sented by the remaining signal \( q \) (Fig. 2). However, it can
Fig. 3: Fluctuation of the direction, $\alpha$, computed from a DVD fragment where a car is passing by with a high speed from one channel to the other. The horizontal axis represents the number of blocks $B$, where $B = 512$. Note that the sampling frequency used in this experiment is equal to 44.1 kHz, and therefore the above fragment has taken 8 seconds approximately.

Matricing

The mapping process, also known as matrixing, is a key issue when dealing with multi-channel sound systems. The system as described so far decodes four channel signals as $L, C, R$ and $S$. The stereo surround in the rear channels can be accomplished by using a decorrelator.

Our adaptive matrix to produce four channel signals is described as:

$$
\begin{bmatrix}
  u_l(k) \\
  u_r(k) \\
  u_c(k) \\
  u_s(k)
\end{bmatrix} =
\begin{bmatrix}
  c_l(k) & w_r(k) & c_c(k) & w_l(k) \\
  -w_l(k) & c_r(k) & 0 & c_s(k) \\
  c_s(k) & 0 & c_c(k) & w_r(k) \\
  c_l(k) & -w_r(k) & c_s(k) & w_l(k)
\end{bmatrix}
\begin{bmatrix}
  y(k) \\
  q(k)
\end{bmatrix}
$$

(12)

where the base signals are computed using a rotation of the input signals:

$$
g(k) = u_l(k)x_l(k) + u_r(k)x_r(k)
$$

$$
q(k) = u_r(k)x_l(k) - u_l(k)x_r(k),
$$

and

\[
\begin{align*}
  e_l &= \begin{cases} 
  -e'_{l_r} & e'_{l_r} < 0 \\
  0 & \text{otherwise}
  \end{cases} \\
  e_r &= \begin{cases} 
  e'_{l_r} & e'_{l_r} \geq 0 \\
  0 & \text{otherwise}
  \end{cases}
\end{align*}
\]

(14)

In this paper, the Lauridsen [6] decorrelator is used to obtain stereo surround because of its simplicity. This decorrelator can be viewed as FIR comb filters with two taps each for surround left and surround right. A time delay of 10 ms is used between the taps, which is determined experimentally.

**CONCLUSION**

A new decoder for multi-channel reproduction of stereo sound based on a novel space mapping is presented. The three-dimensional representation can be used not only as a visual analysis tool for matrix surround sound systems, but also to manipulate such systems to offer user interactivity possibilities.

A new parameter computed using correlation coefficient has been included in the decoder to determine the rear channels distribution. This parameter also solves the ambiguity problem when the direction of a stereo image is indeterminate.
